Abstract

Background: Valvular heart disease (VHD) is an important cause of mortality and morbidity and has been subject to important changes in management. The VHD II survey was designed by the EURObservational Research Programme of the European Society of Cardiology (ESC) to analyze actual management of VHD and compare practice with guidelines.

Methods: Patients with severe native VHD or previous valvular intervention were enrolled prospectively across 28 countries over a 3-month period in 2017. Indications for intervention were considered concordant if the intervention was performed or scheduled in symptomatic patients, corresponding to Class I recommendations specified in the 2012 ESC and in the 2014 American Heart Association/American College of Cardiology VHD guidelines.

Results: 7247 patients (4483 hospitalized, 2764 out-patients) were included in 222 centers. Median age was 71 years (interquartile range 62-80); 1917 patients (26.5%) were aged ≥ 80 years and 3416 were female (47.1%). Severe native VHD was present in 5219 patients (72.0%): aortic stenosis (AS) in 2152 patients (41.2% of native VHD), aortic regurgitation (AR) in 279 (5.3%), mitral stenosis (MS) in 234 (4.5%), mitral regurgitation (MR) in 1114 (21.3%, primary in 746 and secondary in 368) multiple left-sided VHD in 1297 (24.9%) and right-sided VHD in 143 (2.7%). 2028 patients (28.0%) had undergone previous valvular intervention.

Intervention was performed in 37.0% and scheduled in 26.8% of patients with native VHD. The decision for intervention was concordant with Class I recommendations in symptomatic patients with severe single left-sided native VHD in 79.4% (95% confidence interval [CI] 77.1-81.6%) for AS, 77.6% (95% CI 69.9-84.0%) for AR, 68.5% (95% CI 60.8-75.4%) for MS, and 71.0% (95% CI 66.4-75.3%) for primary MR.

Valvular interventions were performed in 2150 patients during the survey; of them, 47.8% of patients with single left-sided native VHD were in New York Heart Association class III or IV. Transcatheter procedures were performed in 38.7% of patients with AS and 16.7% of those with MR.

Conclusions: Despite good concordance between Class I recommendations and practice in patients with aortic VHD, the suboptimal figure in mitral VHD and late referral for valvular interventions suggest the need to improve further guideline implementation.

Key Words: valvular heart disease; echocardiography; valvular surgery; transcatheter interventions; guidelines

Abbreviations and Acronyms

ACC: American College of Cardiology

AHA: American Heart Association

AR: aortic regurgitation

AS: aortic stenosis

CI: confidence interval

CT: computed tomography

EACTS: European Association of Cardiothoracic Surgery

EHS: Euro Heart Survey

EORP: EURObservational Research Programme

ESC: European Society of Cardiology

IQR: interquartile range

MR: mitral regurgitation

MS: mitral stenosis

NYHA: New York Heart Association

VHD: valvular heart disease

TAVR: transcatheter aortic valve replacement

Circulation

Clinical Perspective

What is new?

- Recommendations for interventions in symptomatic patients with severe valve disease are better applied than in the previous European survey conducted in 2001, particularly for aortic valve disease.
- Multimodality imaging is now more frequently used but stress testing remains underused in asymptomatic patients.
- Transcatheter therapies are now widely used in patients with stenotic valve disease.

What are the clinical implications?

- Late referral for interventions shows the need for increasing awareness of valvular heart disease by general practitioners and cardiologists.
- The high burden of elderly patients highlights the need for a multidisciplinary Heart Team approach to assess the risk-benefit ratio of the different modalities of valvular interventions.
- Echocardiographic quantification of regurgitations should be more accurate and pay more attention to quantitative measurements.

Introduction

Valvular heart disease (VHD) affects more than 2% of the population and is associated with increased mortality (1). Its treatment relies mainly on valvular interventions, which have been subject to important changes. The first Euro Heart Survey (EHS) on VHD was conducted in 2001 and provided information on the presentation and management of VHD at that time (2). Since then however, a number of important changes have affected the management of VHD such as the successive release of specific guidelines in Europe and in the US, the introduction of less invasive transcatheter techniques and the introduction of a multidisciplinary Heart Team approach and of Heart Valve Centers of Excellence. However, there has been no large-scale evaluation of the impact of these changes on the current management of VHD. Large national or international registries are now available but focus mainly on transcatheter techniques and do not capture the management process in the whole spectrum of VHD (3-6).

The EURObservational Research Programme (EORP) of the European Society of Cardiology (ESC) conducted the VHD II survey in 2017 with the aim of analysing the management of patients with severe native VHD or previous valvular intervention and to compare these practices with the latest VHD guidelines at that time, published in the 2012 by the ESC/European Association of Cardiothoracic Surgery (EACTS) and in 2014 by the American Heart Association(AHA)/American College of Cardiology (ACC) (7,8), as well as to evaluate changes since the EHS in 2001 (2).

Methods

Study design

The VHD II survey is an international prospective, multicenter, observational study. All the

National Cardiac Society members of the ESC were invited to participate. Participating centers were accepted on a voluntary basis through appointment by National Coordinators. Centers in the same geographical area were grouped into clusters including a variety of sites (university, public and private centers with or without on-site cardiac surgery and/or interventional cardiology) to ensure broad representation. The number of centers and clusters was determined by EORP according to country size. The data, analytic methods, and study materials will be available on reasonable request.

The recruitment period was 3 months for each center, with no limit to the maximum number of patients enrolled. Recruitment began on 16th January 2017 and ended on 28th August 2017, immediately prior to publication of the revised ESC/EACTS guidelines on VHD in order to capture an accurate picture of clinical practice in advance of the guideline update. Six-month follow-up was planned, either during a patient visit or by contact with the treating physician or the patient. Data collected at 6 months were vital status, hospitalizations for cardiac reasons and the performance of a new valvular intervention.

The primary endpoint was the final therapeutic decision for surgical or transcatheter intervention determined during the index hospitalization or outpatient visit.

When required, the study was approved by each national or regional Ethical Committee or Institutional Review Board, according to local regulations. Written informed consent was obtained from all participants. Drug prescription and indications for diagnostic/therapeutic procedures were left at the discretion of the attending physician. Baseline data were collected using a web-based electronic case report form. For patients undergoing intervention during the study period, the type of intervention performed and in-hospital outcome, including mortality, were collected. The survey was overseen by an Executive Committee and managed by the EORP

department of the ESC, which was also responsible for study management, data quality control, and statistical analyses.

Patients

The screened population consisted of patients with severe native VHD as defined by echocardiography using an integrative approach according to guidelines (7,8) or patients with any previous surgical or transcatheter valvular intervention, including percutaneous dilatation. Investigators were asked to include all consecutive hospitalized patients and a complete sample of out-patients presenting to the outpatient clinic 1 day each week (as selected by the center). Patients were included if they fulfilled the following criteria: signed informed consent, age ≥ 18 years, severe native VHD or previous valvular intervention. Exclusion criteria were acute infective endocarditis, enrolment in a valve intervention study impacting on management and VHD related to complex congenital heart disease.

Classification of VHD

Single left-sided VHD was defined as severe VHD affecting a single valve without concomitant moderate or severe VHD on the other ipsilateral valve and sub-classified as aortic stenosis (AS), aortic regurgitation (AR), mitral stenosis (MS) or mitral regurgitation (MR). The association of severe left-sided native VHD with a moderate or severe VHD lesion on the other ipsilateral valve (according to echocardiographic criteria) was classified as multiple left-sided VHD. Isolated right-sided VHD was defined as severe tricuspid or pulmonary VHD without any severe left-sided VHD. Patients presenting with native VHD who had undergone a previous valvular intervention on another valve were classified in the ‘previous valvular intervention’ group to avoid double counting.

Statistical analysis

Descriptive analyses were performed. Continuous variables were reported as median and interquartile range (IQR) and categorical variables as percentages. Comparisons between groups were performed using a chi-2 test for categorical variables and a Kruskal-Wallis test for continuous variables. Survival rates at 6 months were assessed using the Kaplan-Meier method and provided with their 95% confidence interval (CI).

Concordance with guidelines was analyzed in patients with AS and a mean gradient >40 mmHg, severe AR, MS with valve area $\leq 1.5 \text{ cm}^2$ or mean gradient >5 mmHg, and severe primary MR, and expressed by the percentage of patients (with 95% CI) in whom intervention was performed or scheduled among symptomatic patients, which corresponds to conditions fulfilling Class I recommendations for intervention according to both 2012 ESC/EACTS and 2014 AHA/ACC guidelines (7,8). This analysis was also performed according to the type of center.

A two-sided p-value <0.05 was considered statistically significant. All analyses were performed using SAS statistical software version 9.4 (SAS Institute, Inc., Cary, NC, USA).

Results

Enrolment

Twenty-eight ESC countries participated to the VHD II survey. A total of 222 active centers grouped into 108 clusters included 7247 patients (Supplemental Appendix 1); 4483 were inpatients and 2764 out-patients. Reasons for inclusions are detailed in Supplemental Table 1. The majority of patients with native VHD (75.4%) were referred because of a change in clinical status, complications or need for diagnostic evaluation.

The distribution of the types of centers is detailed in Supplemental Figure 1. A cardiac surgery department was present in 60.7% of centers and 85.2% of centers had at least one cardiac catheterization laboratory.

The numbers of patients enrolled were 2418 (33.4%), 2095 (28.9%), 2013 (27.8%) and 503 (6.9%) for Eastern, Western, Southern and Northern Europe, respectively, and 218 (3.0%) in Northern Africa, according to the classification of United Nations. Inclusions per country are detailed in Supplemental Appendix 1.

Patients

The overall median age was 71 years (IQR 62-80); 1917 patients (26.5%) were aged ≥ 80 years, 3416 were female (47.1%) and the median EuroSCORE II was 2.1 (IQR 1.1-4.3). Patient characteristics are detailed in Table 1.

Amongst the 5219 patients with native VHD, 3779 (72.4%) had single left-sided native VHD: AS was most frequent (2152 patients, 41.2% of native VHD), followed by MR (1114 patients, 21.3%, primary MR in 746 and secondary MR in 368), AR (279 patients, 5.3%) and MS (234 patients, 4.5%). Multiple left-sided VHD was present in 1297 patients (24.9% of native VHD) and isolated right-sided VHD in 143 (2.7% of native VHD). Etiologies of left-sided native VHD are summarised in Figure 1. Overall, 67.8% of native VHD was of degenerative etiology, followed by rheumatic heart disease in 11.8%. Of the 368 patients with secondary MR, 190 (51.6%) were classified as ischemic MR and 178 (48.4%) as non-ischemic MR.

Of the 2028 patients who had previously undergone one or more valvular interventions, there were 1665 surgical valve replacements, 622 surgical valve repairs and 335 transcatheter interventions (including 110 percutaneous dilatations).

Patient characteristics and management are detailed according to the 5 regions for patients with native valve disease (Table 2) and for patients with previous valve surgery (Supplemental Table 2). In-patient and out-patient characteristics and management are detailed in Supplemental Table 3.

Investigations

Investigations are described in Table 3. Stress tests were utilized in <5% of all patients and <10% of patients in NYHA class I. Cardiac catheterization was used in 5 to 10% of patients (7.5% in the whole population). The most frequent reasons for performing cardiac computed tomography (CT) were an evaluation before transcatheter aortic valve replacement (TAVR) (78% of AS patients) and assessment of the ascending aorta (94% of AR patients). The results of transthoracic echocardiography for patients with single left-sided native VHD are detailed in Supplemental Table 4.

Decision for intervention and concordance with guidelines

Intervention was considered as indicated in 63.8% (performed in 37.0%, scheduled in another subset of 26.8%) and not indicated by the investigator in 36.2% of patients with native VHD (Table 4). Figure 2 details the percentages of symptomatic patients with severe single left-sided native VHD in whom the intervention was either performed or scheduled. The decision for intervention was concordant with Class I recommendations for symptomatic patients with severe VHD in 79.4% (95% CI 77.1-81.6%) of those with AS, 77.6% (95% CI 69.9-84.0%) with AR, 68.5% (95% CI 60.8-75.4%) with MS, and 71.0% (95% CI 66.4-75.3%) with primary MR. The concordance with class I recommendations in symptomatic patients is described according to the type of center in Supplemental Figure 2.

Interventions performed during the study period

Valvular interventions were performed in 2150 patients during the recruitment period (Table 5).

Of the 1435 patients with single left-sided native VHD undergoing intervention, 686 (47.8%) were in NYHA class III or IV and 230 (16.0%) had signs of congestive heart failure. Patients with MR were frequently operated upon at an advanced stage of disease, as attested by high rates of heart failure, atrial fibrillation and reduced left ventricular ejection fraction.

With regards to the mode of intervention (Table 6), transcatheter procedures were performed in 38.7% of patients with AS and 16.7% of those with MR. Of the 59 transcatheter interventions for MR, 58 were edge-to-edge repairs. Percutaneous mitral balloon commissurotomy was performed in 45.0% of patients with MS and surgical valve repair in 55.7% of patients with primary MR. Bioprostheses accounted for 62.1% of surgical implants in the aortic position and 36.5% in the mitral position. At least one non-valvular surgical procedure was associated with valvular intervention in 506 (23.5%) patients. Concomitant tricuspid valve surgery was performed in 31.7% of patients who underwent interventions for mitral VHD. When considering only surgical interventions, 50.0% of patients with MS and 39.3% with primary MR underwent concomitant tricuspid surgery.

Overall in-hospital mortality after intervention was 2.1% (41/1973) with a median EuroSCORE II of 2.0, IQR [1.1-4.0].

Six-month follow-up

Overall, 97 patients died during the index hospitalization. Of the 7150 patients discharged alive, vital status at 6 months was known in 6373 (89.1%) of them: 6075 (95.3%) were alive and 298 (4.7%) died between hospital discharge and 6 months. Detailed 6-month follow-up was available

in 6137 patients who represented 84.7% of the whole population (7247 patients) and 85.8% of the 7150 patients who were discharged alive from the index hospitalization.

Six-month Kaplan-Meier survival rates were 93.5% (95% CI 92.2-94.5%) for AS, 97.5% (95% 94.5-98.9%) for AR, 96.6% (95% CI 92.6-98.5%) for MS, 94.1% (95% CI 91.9-95.7%) for primary MR, 88.0% (95% CI 83.7-91.2%) for secondary MR, 90.7% (95% CI 88.8-92.3%) for multiple left-sided VHD, 91.3% (95% CI 84.3-95.2%) for isolated right-sided VHD, and 95.3% (95% CI 94.2-96.2%) for patients with previous valvular intervention.

Hospitalization was needed for cardiac reasons during follow-up in 1590/5957 patients (26.7%). The most frequent reason was new valvular intervention, most often planned during index hospitalization. Heart failure was the second most frequent reason for hospitalization during follow-up. Mortality and hospitalizations according the type of valvular disease are detailed in supplemental Table 5.

Of the 1506 patients who had an intervention scheduled but not performed during the index hospitalization (Table 4), information on new valvular intervention during 6-month follow-up was available in 1222 (81.1%). Of them, 527 patients (43.1%) underwent a valvular intervention during 6-month follow-up: 48.1% for AS, 42.9% for AR, 46.2% for MS, 37.0% for MR, 36.6% for multiple left-sided VHD, 33.3% for isolated right-sided VHD and 39.3% for previous valvular intervention.

Discussion

This contemporary survey reinforces the findings of the 2001 EHS on VHD in demonstrating the predominance of degenerative AS and MR, the high frequency of elderly patients with VHD and the inherent burden of comorbidities. Multimodality imaging is represented mainly by the use of

CT in aortic VHD, while physiological assessment (*i.e.* stress tests) is seldom used. The concordance between Class I indications for interventions in symptomatic patients and practice is good for aortic VHD and suboptimal for mitral VHD. Transcatheter interventions are now largely used in the treatment of left-sided native VHD. The most important differences with the EHS on VHD and the VHD II are summarized in Supplemental Table 6.

Population

As was observed in the original 2001 EHS (2), Northern Europe was under-represented, in particular due to mandatory national registries, and there was otherwise a good balance between Eastern, Western and Southern Europe. The distribution of VHD was similar to the EHS, which also included moderate native VHD, and the distribution between native VHD and previous valvular intervention was the same. The proportion of native VHD patients with AS increased from 33.9% in 2001 to 41.2% in 2017, probably as a consequence of population ageing, as the prevalence of AS increases sharply in the elderly (9). It may also reflect increased awareness of AS and the availability of TAVR in patients at high-risk for surgery who were frequently denied or not referred for surgery. The falling proportion with MS is related to the continuous decline of rheumatic fever in Europe, since MS remains predominantly of rheumatic origin. This distribution of native VHD is consistent with the findings of a recent nationwide Swedish registry based on hospital discharge codes and thereby excluding any assessment of VHD severity (10). Here, the only discrepancy concerns the frequency of AR which was higher in the Swedish registry. This may be due to inclusion of patients referred for aneurysm of the ascending aorta and mild or moderate AR, which were not included in the VHD II survey.

Consistent with the predominance of degenerative VHD, elderly patients were affected frequently by most types of VHD. More than a quarter of all patients (26.5%) were aged ≥ 80

years, while they accounted for only 8.3% in the 2001 EHS. Comorbidities, as assessed by the Charlson index, were most frequent in patients with AS and multiple VHD where patients were the oldest.

There were important differences with regards to patient presentation according to the 5 regions. Patients were younger in Eastern Europe and Northern Africa where the frequency of rheumatic heart disease was higher than in Northern and Western Europe. This was particularly marked in Northern Africa, where 72% of native VHD was of rheumatic origin with a particularly high frequency of MS. However, median patient age was 75 years in Southern Europe although the frequency of rheumatic heart disease was >10%. Patients referred to the outpatient clinic were younger, presented with less severe symptoms and less severe comorbidities than those requiring hospitalization.

Importantly, patients with native VHD were still referred at a late stage of the natural history, with >40% in NYHA class III/IV at the time of assessment (except for AR) and 10-30% requiring hospitalization for heart failure within the preceding year. Late referral was more frequent for hospitalized patients than for out-patients. As expected, patients with secondary MR presented frequently with heart failure and left ventricular dysfunction. Late referral may be due to a number of factors, including insufficient awareness of VHD amongst patients and practitioners, insufficient detection related to underuse of auscultation, deferred referral related to inappropriate evaluation of severity and/or symptoms, use of medical therapy despite lack of evidence (with the exception of secondary MR) and inappropriate analysis of risk-benefit ratio of valvular interventions, as confirmed by surveys among patients, general practitioners and cardiologists (11-13). Population-based studies have also shown that VHD is frequently undiagnosed in the community (1,14).

Investigations

According to Supplemental Table 4, valve area and mean gradient were available in most patients with single left-sided stenotic VHD patients (>85% and >90%, respectively).

Conversely, quantitative measurement of regurgitation was available in <45% and <60% of patients with AR and MR, respectively. In addition, approximately 10% of patients with AR and MR were classified as “moderate” according to echocardiographic quantification and were excluded from the analysis of the concordance with guidelines. Overall, the adherence to the recommendations of guidelines on quantification using echocardiography is suboptimal in patients with regurgitant VHD (15,16).

Transesophageal echocardiography was performed in approximately 30% of patients with mitral VHD. CT was used mainly in patients with aortic VHD before TAVR or for assessment of the ascending aorta. A striking finding was the under-utilisation of stress testing, particularly in asymptomatic patients with severe native VHD. Stress tests were used in only 2.9% of patients with native VHD and 5.6% in asymptomatic patients, while they were used in 8.9% of patients with native VHD in 2001 (2). Even with the growing interest for the use of cardiac magnetic resonance for the evaluation of VHD, in particular in regurgitant and right-sided VHD (16,17), its use remained limited to <10% of patients. Rates of diagnostic cardiac catheterization in native VHD fell from >30% in 2001 to 7.5% in 2017. This is now more consistent with the guidelines recommendations to restrict its use to situations where non-invasive evaluation is inconclusive or discordant with clinical findings (7,8).

Decision for intervention

A decision for intervention was taken in the majority of patients with left-sided native VHD, and

more frequently for valvular stenosis than for regurgitation. An intervention was indicated in only 18.9% of patients with isolated right-sided VHD.

We chose to analyze the concordance between guidelines and interventions only in symptomatic patients with severe single left-sided VHD since this corresponds to class I indications in the ESC/EACTS as well as AHA/ACC guidelines, while there are discrepancies between guidelines with regards to indications for intervention in asymptomatic patients (7,8).

Almost 80% of patients with symptomatic aortic VHD and a Class I indication for intervention had one performed or scheduled. In the 2001 EHS, surgery was considered in only 66% of symptomatic patients aged ≥ 75 years with severe AS (18). This was consistent with other contemporary studies performed when surgical aortic valve replacement was the only treatment of AS, which reported that at least a third of patients with severe AS were not referred for surgery (19,20). The present findings may relate to the availability of specific ESC guidelines on VHD in 2007 and 2012, while the 1997 ACC/AHA guidelines were the only guidelines available in 2001 concerning the management of VHD. It is also likely that the availability of TAVR leads enables clinicians to consider intervention in a wider range of patients with AS. The concordance between Class I indications and practice was only 68.5% and 71.0% in symptomatic patients with severe primary MR or MS. This is consistent with the rates of mitral valve surgery in MR in other studies conducted in hospital setting (21,22) or surveys among practitioners (12,13,23,24). The underuse of interventions in MR was even more marked in a recent study performed in a community setting, thereby taking also into account patient management before referral to the hospital (25). Nevertheless, even in mitral VHD, referral for intervention is increasing as compared with the original EHS, in which only 51% of patients with severe symptomatic MR were referred (21). There was no major difference in the concordance between recommendations

and practice according to the type of center. An intervention was scheduled or performed in only 38.3% of patients with secondary MR, consistent with the restricted indications in guidelines compared with primary MR (7,8).

The low rate of interventions in patients who had undergone previous valve intervention is consistent with the finding that the majority of them were referred for routine follow-up. Similarly, the rate of indications for interventions was low in out-patients, who were more frequently referred for follow-up than in-patients.

Interventions performed during the study period

Patients frequently underwent valvular intervention at an advanced stage of disease, as shown by the 50.9% of patients with native VHD operated in NYHA class III-IV, while the corresponding figure was 55.0% in 2001 (2). This observation was particularly marked in patients with MR and consistent with the rate of interventions among patients with a Class I indications for surgery. Non-surgical treatment of VHD was widely used in stenotic VHD and in 11.4% of primary and 32.2% of patients with secondary MR. The respective rates of surgical aortic valve replacement and TAVR are consistent with other contemporary European registries (26). Between 2001 and 2017, the rate of surgical valve repair increased from 46.5% to 51.1% for MR (55.7% for primary MR) and from 1.7% to 21.5% for AR. Increased rates of combined tricuspid and mitral valve surgery may reflect growing awareness of the clinical relevance of associated tricuspid regurgitation.

The observed low mortality rates after intervention are consistent with the overall low-risk profile of this population (median EuroSCORE II 2.0), consistent with other large databases and registries of patients with AS and MR (26-28). Values of predicted and observed mortality

are in accordance with previous studies showing the good predictive performance of EuroSCORE II in patients with VHD (29,30).

Follow-up

Six-month survival rates ranged between 88.0% and 97.5%. Among the single left-sided native VHD, the lowest rates were observed in patients with AS and MR which can be related to the type of VHD but also to the age of patients in these subgroups. The distribution of 6-month survival rates in the VHD II survey is close to corresponding 1-year survival rates previously observed in the EHS (31). After valvular interventions planned during the index hospitalization, heart failure was the most frequent cause of hospitalization for cardiac reasons during follow-up. The frequent occurrence of heart failure during follow-up can be related to the fact that patients were referred at an advanced stage of their disease. Rates of heart failure and mortality may also be due to delayed intervention. Only 48.1% of patients requiring scheduled intervention for AS actually underwent treatment within 6 months, despite the fact that prolonged waiting time for intervention is associated with increased mortality (32). Even patients who undergo valvular intervention may develop heart failure, in particular when intervention is performed in old and highly symptomatic patients (33,34).

Limitations

The VHD II survey is not a comprehensive population-based epidemiological study but a voluntary survey. Representativeness is therefore sub-optimal and selection bias cannot be excluded. Nationwide registries based on hospital discharge codes ensure representativeness but do not provide information on either the severity of VHD or symptomatic status of the patients and cannot be used for assessing the application of guidelines. Nevertheless, inclusion of 28

countries and a wide spectrum of healthcare structures in the VHD II survey provide an in-depth insight into the contemporary presentation and management of VHD.

In the absence of on-site data monitoring, there was no direct control on consecutive patient inclusion and data accuracy. This was partly compensated by multiple checks for consistency with the case report form and queries sent to investigators when data were missing or inconsistent. It is not possible to exclude survival bias in the analysis of 6-month follow-up, which was not available in 10.9% of patients.

Conclusions

This contemporary survey of patients referred with severe VHD within a wide panel of healthcare structures is unique since it was specifically designed to assess current clinical practices and guideline implementation. It shows a growing part of elderly patients. We demonstrate that there is room for improvement in the quantification of valvular regurgitation and considerable underuse of stress tests in asymptomatic patients. Overall, however, Class I recommendations for intervention in symptomatic patients are better applied in comparison with the 2001 EHS, particularly for aortic VHD. Nevertheless, a large proportion of patients are still referred at a late stage of their disease (particularly those with primary MR), thereby highlighting the need for increased awareness of VHD amongst patients, general practitioners and cardiologists. The implementation of guidelines and the wide use of transcatheter techniques are likely to have contributed to more appropriate interventions in VHD since 2001. Following educational initiatives, dedicated surveys play a key role in the assessment of guidelines implementation to improve patient outcome.

*The complete list of Investigators is given in the Appendix.

Acknowledgments

We are indebted to all investigators and the EORP VHD II team: Mrs Souad Mekhaldi (Clinical Project Manager), Mrs Katell Lemaitre (Project Officer), Mr Sébastien Authier (Data Manager), Mrs Cécile Laroche (Statistical Analyses) and Mr Hervé Druais (EORP Head of Department).

Sources of Funding

Since the start of EORP, the following companies have supported the programme: Abbott Vascular Int. (2011–2018), Amgen Cardiovascular (2009–2018), AstraZeneca (2014–2020), Bayer AG (2009–2018), Boehringer Ingelheim (2009–2019), Boston Scientific (2009–2012), The Bristol Myers Squibb and Pfizer Alliance (2011–2019), Daiichi Sankyo Europe GmbH (2011–2020), The Alliance Daiichi Sankyo Europe GmbH and Eli Lilly and Company (2014–2017), Edwards Lifesciences (2016–2019), Ferrer Internacional S.A. (2016–2019), Gedeon Richter Plc. (2014–2016), Menarini Int. Op. (2009–2012), MSD-Merck & Co. (2011–2014),

Novartis Pharma AG (2014–2020), Novo Nordiask AS (2016-2019), Pfizer Ltd. (2015-2018), ResMed (2014–2016), Sanofi (2009–2018), Servier (2009–2018).

Disclosures

B.I. reports personal fees from Edwards Lifesciences, Boehringer Ingelheim and Novartis, outside the submitted work. V.D. reports speaker fees from Abbott Vascular and Boehringer Ingelheim, outside the submitted work. The Department of Cardiology of the Leiden University Medical Center receives unrestricted research grants from Biotronik, Boston Scientific, Medtronic, Edwards Lifesciences and GE Healthcare. J.B. does not have personal conflict of interest to report. B.P. reports unrestricted research grants from Edwards Lifesciences and personal fees from Edwards Lifesciences and Boston Scientific, outside the submitted work.

A.A. reports personal fees from Royal Philips, outside the submitted work. M.H. reports research grants and personal fees from Biotronik, Abbott and Cardiac Dimensions, personal fees from Orbus Neich and Philips/Volcano, outside the submitted work. G.H. reports research grants from Abbott, Biotronik, Boston Scientific and Medtronic, outside the submitted work. F.R. reports research grants and personal fees from SJM / Abbott and Sanofi, personal fees from Servier, Zoll, AstraZeneca, Novartis, Amgen, BMS, Pfizer, Fresenius, Vifor, Roche, Bayer and Böhringer Ingelheim, outside the submitted work. S.W. reports research grants from Boston Scientific, St. Jude Medical, Abbott, Amgen Inc., Biotronik, Terumo Inc., Symetis SA, Edwards Lifesciences and Bayer AG, outside the submitted work. A.M. reports personal fees from Novartis, Bayer and Fresenius, outside the submitted work. A.V. reports personal fees from Abbott Vascular, Edwards Lifesciences and MitralTech, outside the submitted work. Other co-authors have nothing to disclose.

Values are n (%)

*: the total of procedures is higher than the number of patients due to multiple-valve procedures (only left-sided procedures are considered).

Figure Legends

Figure 1. Etiologies of left-sided native valvular heart diseases.

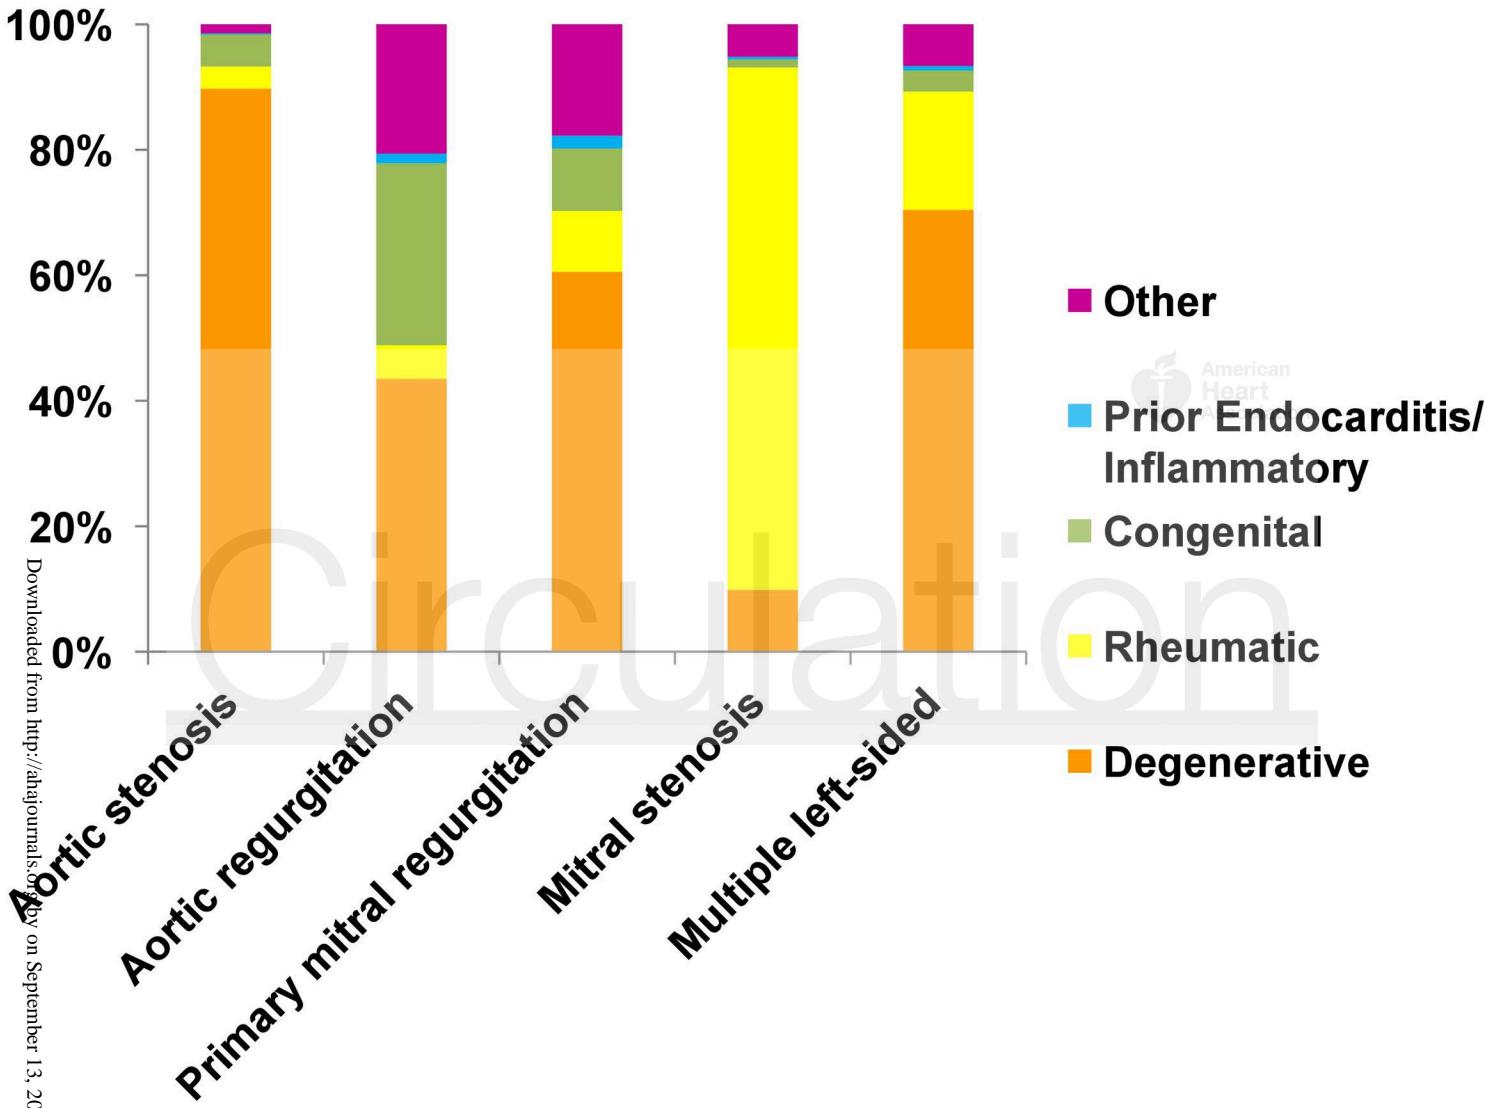

Figure 2. Concordance between Class I indication according to 2012 ESC/EACTS Guidelines and 2014AHA/ACC guidelines (7,8) and performed or scheduled intervention in symptomatic patients with severe single left-sided valvular disease: percentages and 95% confidence intervals (CI).

Symptomatic patients were in NYHA class \geq II or had angina if they had aortic stenosis.

Severe valvular heart disease was defined as follows:

- aortic stenosis: mean gradient >40 mmHg,
- mitral stenosis: valve area ≤ 1.5 cm 2 or mean gradient >5 mmHg,
- aortic and primary mitral regurgitations: classified as severe according to echocardiographic criteria.

American
Heart
Association

Intervention Class I % [95% CI]

Aortic stenosis

1009 1271 79.4 [77.1-81.6]

Aortic regurgitation

114 147 77.6 [69.9-84.0]

Mitral stenosis

115 168 68.5 [60.8-75.4]

Primary mitral
regurgitation

294 414 71.0 [66.4-75.3]
